Abstract

Past emission controls in the UK have substantially reduced precursor emissions of health-hazardous fine particles (PM$_{2.5}$) and nitrogen pollution detrimental to ecosystems. Still, 79% of the UK exceeds the World Health Organization (WHO) guideline for annual mean PM$_{2.5}$ of 5 μg m$^{-3}$ and there is no enforcement of controls on agricultural sources of ammonia (NH$_3$). NH$_3$ is a phytotoxin and an increasingly large contributor to PM$_{2.5}$ and nitrogen deposited to sensitive habitats. Here we use emissions projections, the GEOS-Chem model, high-resolution datasets, and contemporary relationships between exposure and risk of harm to assess the potential human and ecosystem health co-benefits in 2030 relative to the present day of adopting legally required or best available emission control measures. We estimate that present-day annual adult premature mortality attributable to exposure to PM$_{2.5}$ is 48,625, that harmful amounts of reactive nitrogen deposit to almost all (95%) sensitive habitat areas, and that 75% of ambient NH$_3$ exceeds levels safe for bryophytes. Legal measures decrease the extent of the UK above the WHO guideline to 58% and avoid 6,800 premature deaths by 2030. This improves with best available measures to 36% of the UK and 13,300 avoided deaths. Both legal and best available measures are insufficient at reducing the extent of damage of nitrogen pollution to sensitive habitats, as most nitrogen emitted in the UK is exported offshore. Far more ambitious reductions in nitrogen emissions (>80%) than is achievable with best available measures (34%) are required to halve excess nitrogen deposition to sensitive habitats.
UK public health and ecosystem benefits of currently legislated versus best available emission control measures

Key Points:
• Efficacy of UK legal and technological control measures tested with emissions projections, GEOS-Chem, and new exposure-harm relationships
• Both reduce public exposure to particulate matter pollution and avoid 6,800 adult early deaths with legislation and 13,300 with technology
• Neither is sufficient at lessening sensitive habitat exposure to harmful loads of nitrogen and concentrations of phytotoxic ammonia
Abstract
Past emission controls in the UK have substantially reduced precursor emissions of health-hazardous fine particles (PM$_{2.5}$) and nitrogen pollution detrimental to ecosystems. Still, 79% of the UK exceeds the World Health Organization (WHO) guideline for annual mean PM$_{2.5}$ of 5 μg m$^{-3}$ and there is no enforcement of controls on agricultural sources of ammonia (NH$_3$). NH$_3$ is a phytotoxin and an increasingly large contributor to PM$_{2.5}$ and nitrogen deposited to sensitive habitats. Here we use emissions projections, the GEOS-Chem model, high-resolution datasets, and contemporary relationships between exposure and risk of harm to assess the potential human and ecosystem health co-benefits in 2030 relative to the present day of adopting legally required or best available emission control measures. We estimate that present-day annual adult premature mortality attributable to exposure to PM$_{2.5}$ is 48,625, that harmful amounts of reactive nitrogen deposit to almost all (95%) sensitive habitat areas, and that 75% of ambient NH$_3$ exceeds levels safe for bryophytes. Legal measures decrease the extent of the UK above the WHO guideline to 58% and avoid 6,800 premature deaths by 2030. This improves with best available measures to 36% of the UK and 13,300 avoided deaths. Both legal and best available measures are insufficient at reducing the extent of damage of nitrogen pollution to sensitive habitats, as most nitrogen emitted in the UK is exported offshore. Far more ambitious reductions in nitrogen emissions (>80%) than is achievable with best available measures (34%) are required to halve excess nitrogen deposition to sensitive habitats.

Plain Language Summary
Particulate matter pollution is detrimental to human health, nitrogen pollution offsets ecosystem balance of sensitive habitats, and ammonia is toxic to plants. Here we determine the potential public health and ecosystem benefits of adopting currently legislated or best available emission control measures. We use state-of-science air quality and exposure assessment models and high-resolution datasets to estimate air pollution abundances and deposition and determine risk of human and ecosystem harm from air pollution in the UK. We find that substantial improvements to public health result from currently legislated measures, estimated as the number of avoided early deaths attributable to decline in particular matter pollution. The number of avoided deaths doubles with best available emission control measures, as these also target particulate matter precursor emissions of ammonia from agricultural activity not mandated by existing legislation. The benefits to sensitive habitats of either legal or best available measures is near-negligible. Mitigating harm to ecosystems will require major advances in emission mitigation technologies.

1 Introduction
Air pollution is a leading global burden of disease (Cohen et al., 2017; Vohra et al., 2021) and is detrimental to ecosystem balance (Sala et al., 2000; Phoenix et al., 2012). In the UK, about 29,000 adult premature deaths have been attributed to long-term exposure to ambient fine particulate matter pollution (PM$_{2.5}$) in a single year (Gowers et al., 2014) and most (70%) sensitive habitats with low nutrient needs are susceptible to harm from deposition of excessive amounts of nitrogen (Rowe et al., 2022). Anthropogenic emissions of ammonia (NH$_3$), overwhelmingly (~90%) from agriculture, are a large and often dominant component of PM$_{2.5}$ in densely populated cities (Kelly et al., 2023; Vieno et al., 2016) and of nitrogen deposited to ecosystems (Tomlinson et al., 2021). NH$_3$ is also a phytotoxin (Dise et al., 2011; van Herk et al., 2007; Krupa, 2003).
Measures to reduce NH₃ emissions from agricultural activity in the UK are limited to voluntary implementation of documented best practices (DEFRA, 2018). Over the past 3 decades (1990-2020) anthropogenic NH₃ emissions have declined by just 0.6% a⁻¹; much slower than decline in other PM₂.₅ precursors such as sulfur dioxide (SO₂) at 3.0% a⁻¹ and nitrogen oxides (NOₓ) at 2.4% a⁻¹ (Churchill et al., 2022). NH₃ is a semi-volatile, alkaline gas that partitions reversibly to acidic aerosols forming ammonium (NH₄). Due to sustained controls on local and national SO₂ and NOₓ sources, concentrations of acidic sulfate aerosols formed from SO₂ oxidation and acidic nitrate aerosols formed from NOₓ oxidation have declined, contributing to decline in NH₄ (Tang et al., 2018). Weakening of the NH₃ aerosol sink and absent controls on agriculture have caused an increase in ambient NH₃ concentrations and the amount of NH₃ deposited to terrestrial ecosystems via dry and wet deposition (Hertel et al., 2012). This has been detrimental to habitats sensitive to excessive nitrogen loads and exposure to NH₃. The latter includes bryophytes, a prevalent class of plants in the UK adversely affected by NH₃ at relatively low concentrations (~1 μg m⁻³) (Cape et al., 2009).

The UK commits to sustained decline in air pollutant precursor emissions as a signatory of the United Nations Economic Commission for Europe (UNECE) Convention on Long-Range Transboundary Air Pollution (CLRTAP) legislated through the UK National Emission Ceilings Regulations (UK, 2018). The UK met the 2020 targets, according to bottom-up estimates from the National Atmospheric Emission Inventory (NAEI) (Richmond et al., 2020), though top-down NH₃ emissions estimated with satellite observations suggest the NAEI may underestimate NH₃ emissions by 30-50% (Marais et al., 2021). NH₃ emissions targets, reported as percent reduction relative to 2005, are 8% in any year in 2020 to 2029 and 16% from 2030; modest in comparison to SO₂ (59% in 2020-2029 and 79% from 2030) and NOₓ (42% in 2020-2029 and 63% from 2030) (Office of the European Union, 2016a). Readily available emission control measures targeting the largest agricultural sources of NH₃, fertiliser use and livestock and manure management (Churchill et al., 2022), include low nitrogen livestock feed, covered manure storage, low emissions methods of spreading manure, filters and scrubbers of air ventilated from animal housing, and low NH₃ alternatives to urea-based fertilisers (Backes et al., 2016). Efficacy of these range from 10-20% decrease in emissions for low nitrogen feed, to 80% decrease for air filtration and covered manure storage, to up to 93% for phasing out urea-based fertilizers (Klimont & Brink, 2004).

Past studies that have assessed separately the public health and ecosystem benefits of emissions controls suggest current measures offer greater benefits to public health than the expense to implement (Giannakis et al., 2019), and that mitigating harm to sensitive ecosystems would require large (at least 40%) reductions in NH₃ emissions (Woodward et al., 2022). Here we investigate whether adoption of measures to meet current legislation or of readily available maximum technically feasible technologies across all sectors, including agriculture, are sufficient to offer combined benefits to public health and sensitive habitats in the UK. We do this by implementing emissions scenarios from the EU’s Evaluating the Climate and Air Quality Impacts of Short-Lived Pollutants (ECLIPSE) project (Stohl et al., 2015) in the GEOS-Chem model to simulate the response of ambient PM₂.₅ and NH₃ and nitrogen deposition to emissions changes. We apply these to high spatial resolution datasets of contemporary nitrogen deposition to sensitive habitats and models of the relationship between exposure and risk of harm to calculate adult premature mortality in each UK administrative area and the scale of harm to sensitive habitats.
2 Materials and Methods

2.1 GEOS-Chem Model Description

We use the GEOS-Chem chemical transport model (CTM) version 13.0.0 (https://doi.org/10.5281/zenodo.4618180; accessed 12 December 2021) to simulate present-day and future UK surface concentrations of PM$_{2.5}$ and NH$_3$ and total (wet and dry) nitrogen deposition due to emissions controls adopted across Europe. The future scenarios are representative of emissions likely in 2030 from adopting either (1) currently legislated emission controls or (2) maximum technically feasible measures. In what follows, the scenarios and associated model results are labelled “PD” for the present-day simulation in 2019, “CLE” for adopting measures to meet current legislation by 2030 and “MTF”, also for 2030, but following adoption of maximum technically feasible measures. The model is nested over the UK (49.25°N to 59.50°N, 9.375°W to 3.75°E) at 0.25° × 0.3125° (28 km latitude × 20 km longitude at the centre of the domain) and is updated 3-hourly with boundary conditions from a global GEOS-Chem simulation at 4° × 5°. The model uses GEOS-FP assimilated meteorology from the NASA Global Modelling and Assimilation Office. All simulations are driven with meteorology for the same year (2019) to isolate the effect of changes in anthropogenic emissions only. The year 2019 instead of 2020 is chosen for the PD simulation, as it is unaffected by the brief, but dramatic decline in emissions resulting from lockdown measures in the first wave of the COVID-19 pandemic in Spring 2020 (Potts et al., 2021).

Anthropogenic emissions in the PD simulation are mostly consistent with those detailed in Kelly et al. (2023) from an earlier model version (v12.1.0) for the same year (2019) used to characterise sources contributing to PM$_{2.5}$ in UK cities. These emissions are from the NAEI for the UK and the European Monitoring and Evaluation Programme (EMEP) for all other European countries. Emissions scaling is applied to terrestrial NAEI and EMEP SO$_2$ emissions to address a positive bias in modelled SO$_2$ surface concentrations (Marais et al., 2021) and to NAEI and EMEP NH$_3$ emissions to resolve differences between bottom-up emissions and those derived with satellite observations of NH$_3$ column densities (Marais et al., 2021). The scale factors applied are a uniform 60% decrease in land-based SO$_2$ emissions and 50% increase in NH$_3$ emissions. The NH$_3$ emissions scaling is supported by agreement between the model and surface observations of NH$_4$ concentrations at rural sites throughout the UK with this scaling (Kelly et al., 2023) and, as we show in this work, modelled and observed rainwater concentrations of reduced (NH$_3$ ≡ NH$_3$ + NH$_4$) nitrogen.

For the future (2030) scenario simulations, we scale anthropogenic emissions in all countries in Europe in the PD simulation using projected changes in emissions derived from integrated assessment models. All anthropogenic emissions, except aviation, are from the ECLIPSE project (Stohl et al., 2015). Emissions due to control measures are predicted in five-year intervals from 1990 to 2050 for multiple major pollutants and precursors (SO$_2$, NO$_x$, NH$_3$, primary PM$_{2.5}$, non-methane volatile organic compounds (NMVOCs), and carbon monoxide) and sectors (agriculture, residential, commercial, energy, industry, on- and off-road transport, shipping, and waste). We use data from the latest version of ECLIPSE (v6b; https://previous.iiasa.ac.at/web/home/research/researchPrograms/air/ECLIPSEv6b.html; last accessed 3 August 2022). For the CLE simulation, we use the ECLIPSEv6b ‘CLE’ scenario, as this incorporates changes in anthropogenic emissions due to implementation of mitigation...
measures legislated as recently as 2018. For the MTF simulation, we use the ECLIPSEv6b ‘MTFR’ scenario that assumes adoption of all available air pollution control measures. The ECLIPSEv6b shipping emissions were recently revised to capture a wider range of emission factors for primary particles. Only the CLE emissions were updated, so the same shipping emissions are used for CLE and MTF scenarios. ECLIPSEv6b does not predict aviation emissions, so we take these from Intergovernmental Panel on Climate Change (IPCC) projections downloaded using the Representative Concentration Pathways Database tool version 2.0.5 (https://tntcat.iiasa.ac.at/RcpDb/; last accessed 3 August 2022). The IPCC emissions we use are the business-as-usual Shared Socioeconomic Pathways (SSP) 2-4.5 (Fricko et al., 2017) for the CLE scenario and the sustainable pathways SSP 1-2.6 (van Vuuren et al., 2017) for the MTF scenario. All emissions data are provided as gridded annual values at 0.5º × 0.5º, so we derive annual scale factors to apply to PD emissions at 0.5º × 0.5º resolution. Hourly, monthly and seasonal scaling factors are the same as those used for the PD emissions. The Harmonized Emission Component (HEMCO) processing package (Keller et al., 2014) is used to apply scaling factors and to grid emissions to the GEOS-Chem boundary condition and nested model resolutions.

Natural emissions are the same for all scenarios. These are 0.25º × 0.3125º offline emissions of hourly dust (Meng et al., 2021), biogenic VOCs (Weng et al., 2020), and soil NOx (Weng et al., 2020), and 3-hourly lightning NOx (Murray et al., 2012). Natural NH3 emissions are monthly values from the Global Emissions InitAtive (GEIA) inventory for oceans and soils (Bouwman et al., 1997) and annual values from Riddick et al. (2012) for seabirds. GEIA NH3 emissions are halved to address a known overestimate in these (Paulot et al., 2014).

GEOS-Chem simulates the individual PM2.5 components sulfate, nitrate, NH4, primary and secondary organic aerosols (POA, SOA), black carbon (BC), sea salt, and dust. Formation of sulfate from oxidation of SO2, detailed in Park et al. (2004), is dominated by in-cloud oxidation by hydrogen peroxide. Formation of aerosol nitrate from uptake of nitric acid (HNO3) and aerosol NH4 from reversible partitioning of NH3 is determined with the thermodynamic equilibrium model ISORROPIA-II (Fountoukis & Nenes, 2007). SOA is estimated with fixed mass yields applied to anthropogenic and biogenic NMVOCs emissions (Pai et al., 2020).

Model representation of other PM2.5 components are detailed in Jaeglé et al. (2011) for sea salt and Fairlie et al. (2007) for dust. The proportion of BC and POA emitted as hydrophobic (80% for BC, 50% for POA) ages to hydrophilic at an e-folding time of 1.15 days (Cooke et al., 1999; Chin et al., 2002). Dry deposition is via the Wesely (1989) resistance-in-series scheme. Wet deposition includes scavenging in convective updrafts and rainfall, as well as washout, entrainment and detrainment as detailed in Liu et al. (2001) for water-soluble aerosols and Amos et al. (2012) for gases. We enable the fast scavenging mechanism of Luo et al. (2020) that addresses a positive cold season bias in modelled surface concentrations of aerosol nitrate and NH4 across Europe. Chemical initialization of the model is achieved with spin-ups of a year for global boundary conditions and 2 months for the PD, CLE and MTF nested domain simulations.

The model is sampled from 1 January to 31 December 2019 to calculate annual mean surface concentrations of NH3 and components of PM2.5 and of reduced and oxidized gas and aerosol-phase nitrogen wet and dry deposition fluxes. Surface concentrations of PM2.5 are calculated at standard conditions of temperature (20ºC) and pressure (1 atm) and associated aerosol water is determined using hygroscopic growth factors of individual PM2.5 components representative of
50% relative humidity, as detailed in Kelly et al. (2023). Total nitrogen deposition is calculated as the sum of GEOS-Chem deposition fluxes of reduced and oxidized nitrogen compounds that wet and dry deposit (NH₃, NH₄, HNO₃, aerosol nitrates, peroxy acetyl nitrates, and gas-phase organonitrates) and that only dry deposit (NO₂, dinitrogen pentoxide, and C₁-C₃ alkyl nitrates).

2.2 Surface Observations for GEOS-Chem Evaluation

Kelly et al. (2023) compared UK network measurements of PM$_{2.5}$ to PM$_{2.5}$ obtained with an earlier version of the model driven with similar PD emissions to those detailed in Section 2.1. In that comparison, GEOS-Chem annual mean PM$_{2.5}$ is spatially consistent with the observations (R = 0.66), but with an expected model underestimate (of 11%), as many of the network sites are in cities along busy roads. We compare our PD model output to that of Kelly et al. (2023) archived on the University College London Data Repository (Marais et al., 2022).

We also evaluate model simulation of nitrogen wet deposition with surface network rainwater concentrations of oxidized and reduced nitrogen. These are from rural and semi-rural UK Eutrophying and Acidifying Pollutants (UKEAP) Precipitation Network (Precip-Net) measurement sites established to determine long-term trends in wet deposition of air pollutants. Data at the forty-one sites operational in 2019 are from the UK-Air data portal (https://uk-air.defra.gov.uk/data/data_selector; last accessed 15 March 2023). Samples at these sites are collected every two weeks to record rainwater volume and measure oxidized (nitrate) and reduced (NH₃) nitrogen rainwater concentrations (Kelleghan et al., 2021). We identify and remove observations contaminated by bird strikes (Conolly et al., 2021) and correct biases in GEOS-FP monthly total precipitation (Neelam et al., 2021; Travis et al., 2016; Paulot et al., 2014). Only three samples are contaminated with bird strikes, identified with phosphate (P) rainwater concentrations > 0.1 mg P L$^{-1}$. We correct for biases in GEOS-FP precipitation by multiplying GEOS-FP monthly total precipitation (precip) by the correction factor derived by Paulot et al. (2014) ((precip$_{observed}$/precip$_{modelled}$)$^{0.6}$), where modelled precipitation is for grids coincident with UKEAP sites. We use the corrected modelled rainwater volume and GEOS-Chem wet deposition fluxes to calculate GEOS-Chem nitrate and NH$_x$ rainwater concentrations.

2.3 Public Health Burden Attributable to Exposure to PM$_{2.5}$

We use the hybrid health risk assessment model from Weichenthal et al. (2022) to calculate adult premature deaths attributable to exposure to PM$_{2.5}$ in the PD and by 2030 due to CLE and MTF control measures. The hybrid model we use merges two functions to represent the relationship between PM$_{2.5}$ and relative risk (RR) of adult (25+ years) premature mortality covering a wide PM$_{2.5}$ concentration range. The functions are known as the extended Shape Constrained Health Impact Function (eSCHIF) and Fusion. eSCHIF was derived with Canadian Census Health and Environment Cohort (CanCHEC) study data covering 2.5 to 17.7 μg m$^{-3}$ (Brauer et al., 2022; Weichenthal et al., 2022). Fusion itself is a hybrid of three widely used health-risk assessment models, established to address deficiencies in each (Burnett et al., 2022). As the Fusion function is underconstrained at very low PM$_{2.5}$ concentrations, Weichenthal et al. (2022) used eSCHIF at 2.5-5 μg m$^{-3}$, choosing the recently revised World Health Organization (WHO) guideline value of 5 μg m$^{-3}$ (WHO, 2021) to transition between the two curves. This requires an artificial ~14% increase in Fusion RR$s$ at concentrations relevant to the UK to achieve a continuous
curve. We avoid this by rather adapting the code provided by Weichenthal et al. (2022) to transition at the intersection of the two curves at 9.8 µg m\textsuperscript{-3}.

The eSCHIF RR function we apply from 2.5 to 9.8 µg m\textsuperscript{-3} is:

\[
eSCHIF(z) = \exp \left\{ \frac{\phi \ln \left( \frac{z - z_{cf}}{\alpha} \right)}{1 + \exp \left( \frac{z - z_{cf}}{\nu} \right)} + \omega \ln \left( \frac{z - z_{cf}}{\delta} + 1 \right) \right\}
\]  

(1),

where \( z \) is annual mean PM\textsubscript{2.5}, \( z_{cf} \) is the counterfactual concentration of 2.5 µg m\textsuperscript{-3} at and below which RR = 1, and \( \phi, \alpha, \tau, \nu, \omega \) and \( \delta \) are best-fit parameters derived from the cohort data. The Fusion curve we apply for PM\textsubscript{2.5} > 9.8 µg m\textsuperscript{-3} is:

\[
Fusion(z) = \exp \left\{ \gamma \times (\min(z, \mu) + \int_{\mu}^{Z} \left( 1 + \frac{1-r}{r} \left( \frac{z-\mu}{\theta-\mu} \right)^{\frac{\theta-\mu}{(1-r)}} \right)^{-1} \right) dx + \rho \ln(\max(z, \theta)/\theta) \right\}
\]  

(2),

where \( \gamma, \mu, \rho \) and \( \theta \) are best-fit parameters obtained with the cohort data. PM\textsubscript{2.5} (\( z \)) in Eq. (1) and (2) are PD, CLE and MTF annual means in each GEOS-Chem grid.

Figure 1 shows the shapes of the Fusion and eSCHIF curves and the hybrid of the two for PM\textsubscript{2.5} ≤ 12 µg m\textsuperscript{-3}, the peak measured and modelled annual mean PM\textsubscript{2.5} in the UK in 2019 (Kelly et al., 2023). Fusion is linear at the range relevant to the UK. eSCHIF is supralinear from 2.5 to ~5 µg m\textsuperscript{-3}; a shape supported by epidemiological cohort studies conducted in Europe and North America (Di et al., 2017; Strak et al., 2021).

**Figure 1.** Curves relating relative risk of adult premature mortality to ambient PM\textsubscript{2.5}. Lines are eSCHIF (Eq. (1), grey), Fusion (Eq. (2), blue), the hybrid of the two (red dashed), the Global Exposure Mortality Model (GEMM, green), and curves used in past UK studies by Public Health England (PHE, 2014) (magenta) and Macintyre et al. (2023) (cyan). Arrows point to the WHO 2021 guideline at 5 µg m\textsuperscript{-3} and the intersection of eSCHIF and Fusion at 9.8 µg m\textsuperscript{-3}. 
The RR values obtained with Eq. (1) and (2) are used to calculate the fraction of adult nonaccidental deaths attributable to exposure to PM$_{2.5}$, the attributable fraction ($AF$):

$$AF = \begin{cases} 
1 - \frac{1}{e^{SCIF(z)}} & 2.5 \mu g m^{-3} < z \leq 9.8 \mu g m^{-3} \\
1 - \frac{1}{FUSION(z)} & z > 9.8 \mu g m^{-3} 
\end{cases}$$

These are calculated for each GEOS-Chem grid and further used to estimate adult excess deaths attributable to exposure to PM$_{2.5}$ as the product of $AF$, adult population, and baseline nonaccidental mortality rates ($BMR$):

$$PM_{2.5} \text{ excess deaths} = AF \times \text{Adult Population} \times BMR$$

$BMR$s are from the Global Burden of Disease (GBD) for 2019 to avoid influence from COVID. These are provided in 5-year age increments (https://vizhub.healthdata.org/gbd-results/, last accessed 30 March 2023), where the nonaccidental premature deaths we use are the sum of non-communicable diseases and lower-respiratory infections for adults 25 years and older. These account for 96% of UK total adult premature deaths. $BMR$s are reported for each administrative area in England and at the national scale for Scotland, Wales and Northern Ireland. UK population data for 2019 reported in 5-year age increments at 30 arc-seconds (~1 km) resolution are from WorldPop (https://dx.doi.org/10.5258/SOTON/WP00671; last accessed 5 August 2022). The GBD $BMR$s and cumulative WorldPop data for age-groups 25 years and older are gridded to the GEOS-Chem grid to collocate population and PM$_{2.5}$ pollution hotspots. These gridded data of $AF$s, adult population and $BMR$s are multiplied (Eq. (4)) and the resultant gridded excess deaths are sampled with shapefiles of UK administrative areas (county councils, unitary authorities and metropolitan counties) from the Database of Global Administrative Areas (GADM) (https://gadm.org/; last accessed 17 March 2023). This yields excess deaths in all 184 administrative areas: 119 in England, 32 in Scotland, 22 in Wales, and 11 in Northern Ireland.

We test sensitivity of premature mortality estimates to health-risk assessment model choice by comparing to values obtained with the Global Exposure Mortality Model (GEMM) (Burnett et al., 2018). The GEMM curve, included in Figure 1, is the version obtained without the Chinese Male Cohort, as detailed in Burnett et al. (2018). GEMM is also for adults 25 years and older and has the same counterfactual PM$_{2.5}$ as the hybrid model (RR = 1 at 2.5 $\mu g m^{-3}$). GEMM RRs are less than the hybrid model at PM$_{2.5} < 7 \mu g m^{-3}$ and exceed the hybrid model above this.

### 2.4 Harm to Nitrogen Sensitive Habitats

We assess the efficacy of emission control scenarios at alleviating harm to sensitive habitats by quantifying the change in the amount and extent of nitrogen deposited in excess of sensitive habitat critical loads and the extent of ambient NH$_3 > 1 \mu g m^{-3}$ indicative of harm to bryophytes. Recommended habitat-specific critical loads for the thirteen sensitive habitats in the UK are given in Table 1. These range from 5 kg nitrogen (N) ha$^{-1}$ a$^{-1}$ for low resilience habitats such as bogs and montane habitats to 10 kg N ha$^{-1}$ a$^{-1}$ for more resilient habitats such as calcareous grasslands and all woodlands except Scotts pine. These are revised following a recent review (Bobbink et al., 2022) and now 2-7 kg N ha$^{-1}$ a$^{-1}$ less than previously recommended values
compiled by Hall et al. (2015) for all sensitive habitats except the unmanaged oak and other woodlands habitats that are unchanged. We average the critical loads in Table 1 onto the GEOS-Chem grid using maps of fractional coverage of sensitive habitats provided at 1 km resolution by the UK Centre for Ecology and Hydrology (UKCEH). These gridded critical loads are shown in Figure 2(a). Nitrogen sensitive habitats account for 38% of UK land area, dominated by acid grasslands, dwarf shrub heath and coniferous woodlands. Most (58%) of the nitrogen sensitive areas are in Scotland (Rowe et al., 2022). The total coverage in Table 1 of 92,801 km\(^2\) is 973 km\(^2\) less than is in the critical loads trends report compiled by the UKCEH (Rowe et al., 2022), as the GEOS-Chem UK nested domain excludes Shetland Islands.

\(^a\)Lower end of the range of recently updated values from Rowe & Hina (2023), \(^b\)Percent contribution to UK sensitive area total coverage of 92,801 km\(^2\).

GEOS-Chem is too coarse to resolve deposition to individual sensitive habitats. This is particularly apparent across southern and central England where sensitive habitats account for <20% of GEOS-Chem grid areas (Figure 2(b)). GEOS-Chem wet deposition also does not account for enhanced nitrogen washout from orographic lifting over upland areas (Dore et al., 1992; Fowler et al., 1988). Given this, we use UKCEH Concentration Based Estimated Deposition (CBED) annual multiyear (2018-2020) mean nitrogen deposition rates provided at 5 km resolution to calculate PD nitrogen deposition exceedances. The derivation of this dataset is detailed in Rowe et al. (2022). Briefly, CBED wet deposition fluxes are determined with UK Met Office annual precipitation data and monitoring network observations of ambient reactive nitrogen concentrations and rainwater ion concentrations interpolated to the 5 km CBED grid and by accounting for enhanced wet deposition due to orographic lifting and deposition of cloud droplets to vegetation. Dry deposition is determined with a resistance-in-series model using ammonia concentrations simulated by the EMEP regional CTM at 5 km resolution and vegetation-specific deposition velocities. The CBED deposition data includes nitrogen deposition values for forests and open vegetation. Deposition rates to forests are ~60% more than values for open vegetation,
due to greater surface area of forest vegetation. We map CBED deposition data to the GEOS-Chem grid using UKCEH habitat maps of the spatial coverage of the six woodlands and seven open vegetation habitats in Table 1 before using the gridded deposition data to calculate nitrogen exceedances for the PD. This yields maps of nitrogen deposition in kg N (ha sensitive habitat)$^{-1}$ a$^{-1}$. We then use GEOS-Chem PD, CLE and MTF total nitrogen deposition to calculate changes in nitrogen deposition due to CLE and MTF emission controls.

![Figure 2](image_url)

**Figure 2.** UK nitrogen sensitive habitat critical loads and coverage on the GEOS-Chem grid. Maps are sensitive habitat nitrogen critical loads in kg N (ha sensitive habitat)$^{-1}$ a$^{-1}$ (a) and fractional cover of sensitive habitats in each GEOS-Chem gridcell. Grey circles in (b) are UKEAP Precip-Net monitoring site locations (Section 2.2).

### 3 Results and Discussion

#### 3.1 Emission Control Scenarios and GEOS-Chem Evaluation

Figure 3 shows annual anthropogenic emissions of NH$_3$, NO$_x$, SO$_2$ and primary PM$_{2.5}$ used in GEOS-Chem PD and future (CLE, MTF) simulations. These are totals for the NAEI domain, so include shipping emissions in UK territorial waters. PD emissions total 452 Gg NH$_3$, 712 Gg NO$_x$ as NO, 45 Gg SO$_2$ as S, and 102 Gg primary PM$_{2.5}$. Agriculture accounts for ~90% of anthropogenic NH$_3$, dominated by fertiliser use and livestock and manure management. NO$_x$ is mostly from land transport and shipping and is the only PM$_{2.5}$ precursor with non-negligible contribution from aviation of 5% in the PD. SO$_2$ is mostly from industrial processes, energy generation and shipping (Churchill et al., 2022). Primary PM$_{2.5}$ is mostly from residential and commercial sectors and industry.

All air pollutant precursors except NH$_3$ decline in the CLE scenario by 14% for SO$_2$, 34% for NO$_x$, and 24% for primary PM$_{2.5}$. According to ECLIPSev6b emissions projections, the UK fails to meet its CLRTAP emissions ceilings commitment of 8% decrease in NH$_3$ emissions with
Adoption of maximum technically feasible measures surpasses this commitment, achieving a 19% decrease in NH$_3$ emissions. This is still less than half the minimum decline that Woodward et al. (2022) estimate is needed to significantly mitigate harm to sensitive habitats using less strict critical loads than the updated recommended values (Table 1). The 2% increase in CLE NH$_3$ emissions in Figure 3(a) is due to limited adoption of suggested measures to offset increase in NH$_3$ emissions from intensification of agriculture to meet growing food and market demands (Alexandratos & Bruinsma, 2012). NO$_x$ emissions from shipping for both the CLE and MTF scenarios decrease by 21% due to NO$_x$ emissions regulations adopted in the Baltic and North Seas since 2021 (IMO, 2019). Shipping emissions of SO$_2$ increase by 12% relative to the PD, increasing its contribution to anthropogenic SO$_2$ emissions from 29% for the PD to 38% for the CLE and 54% for the MTF. According to ECLIPSEv6b, large (>70%) reductions in SO$_2$ emissions from switching to low-sulfur fuel occur a decade earlier in 2010-2020 (Office of the European Union, 2016b). Aviation NO$_x$ decreases by 19% in the CLE scenario and increases by 10% in the MTF scenario, due to trade-offs between emissions of NO$_x$ and the greenhouse gas carbon dioxide (Freeman et al., 2018; Skowron et al., 2021). The relative contribution of aviation to total NO$_x$ emissions is 7% for CLE and 11% for MTF.

Figure 3: UK present and future anthropogenic emissions of PM$_{2.5}$ and nitrogen pollution precursors. Panels show total annual emissions of NH$_3$ (a), NO$_x$ (b), SO$_2$ (c), and primary PM$_{2.5}$ (d) for PD and future (2030) CLE and MTF emissions scenarios. Primary PM$_{2.5}$ is the sum of BC, POA and dust. Inset values are percent change in CLE and MTF relative to PD. Bar colours distinguish surface-bound terrestrial anthropogenic sources (blue), ships (red), and aircraft (yellow).
Figure 4(a) shows GEOS-Chem PD annual mean PM$_{2.5}$. Grids have the same spatial distribution (R = 0.99) and average only 6% or 0.4 µg m$^{-3}$ more than is simulated with the model version from Kelly et al. (2023) (Section 2.2). Monthly UK mean PM$_{2.5}$ in this work ranges from 0.6 µg m$^{-3}$ less (February) to 1.9 µg m$^{-3}$ more (April) than is obtained by Kelly et al. (2023). These differences are due to more efficient cold season wet deposition of nitrate and NH$_4$ and less extreme downscaling of SO$_2$ emissions in this work. The latter enhances formation of springtime inorganic sulfate, nitrate and ammonium aerosol. As in Kelly et al. (2023), 79% of GEOS-Chem grids in Figure 4(a) exceed the WHO 2021 annual mean PM$_{2.5}$ guideline of 5 µg m$^{-3}$.

**Figure 4.** Effect of emission control measures on UK PM$_{2.5}$. Maps are GEOS-Chem annual mean PM$_{2.5}$ in 2019 (PD) (a) and changes in PM$_{2.5}$ relative to the PD due to controls on anthropogenic sources to meet current legislation (CLE minus PD) (b) and adoption of readily available maximum technically feasible measures (MTF minus PD) (c). Inset numbers in (b) are locations with greatest decline in PM$_{2.5}$ discussed in the text: 1. London, 2. Birmingham, 3. Manchester and Leeds, 4. East Yorkshire, and 5. south coast of Wales.

Figure 5 compares observed and modelled rainwater concentrations of nitrate and NH$_x$ to assess GEOS-Chem PD nitrogen wet deposition at UKEAP monitoring sites (Figure 2(b)). Temporal coverage at all sites exceeds 75%. Site mean UKEAP rainwater concentrations are 0.34 mg N L$^{-1}$ for nitrate and 0.42 mg N L$^{-1}$ for NH$_x$. The correction applied to GEOS-FP total precipitation (Section 2.2) leads to changes in GEOS-FP rainwater volume that varies from a 40-50% increase in December and January, to a 23-26% decrease in April and July, to near-negligible (4-6%) difference in March and November. The overall effect on total rainwater volume in 2019 is a small 4% increase. Without the correction, the correlation between modelled and observed NH$_x$ is weak (R = 0.47) and there is an apparent underestimate in the model of 33% for nitrate and 22% for NH$_x$. With the rainwater volume correction, both nitrate (R = 0.85) and NH$_x$ (R = 0.64)
are spatially consistent, modelled nitrate is 15% or 0.05 mg N L$^{-1}$ less than is observed, and modelled and observed NH$_x$ are equivalent. A 15% difference in oxidized NO$_x$ is more than the prescribed 8% error in NAEl NO$_x$ emissions (Richmond et al., 2020), but in agreement with a low bias in NAEl NO$_x$ emissions when compared to top-down emissions derived with satellite observations of tropospheric columns of nitrogen dioxide (NO$_2$) (Pope et al., 2022).

Figure 5. Evaluation of modelled nitrogen wet deposition. Scatterplot compares observed (UKEAP) and modelled (GEOS-Chem) rainwater concentrations of oxidized (nitrate, red) and reduced (NH$_x$, blue) nitrogen at UKEAP sites in 2019. The grey line is the 1:1 relationship and the black dashed lines bound the 50% difference. Numbers inset are the Pearson’s correlation coefficient (R) and the model normalized mean bias. Site locations are in Figure 2(b).

The contribution of wet deposition to total nitrogen deposition is 58% for grids coincident with UKEAP sites. Many of these sites evaluate model grids dominated by sensitive areas, particularly in Scotland (Figure 2(b)). The 58% contribution to total deposition is similar (57%) for all UK grids and includes contributions from NH$_3$ (31%), HNO$_3$ (28%), NH$_4$ (25%) and aerosol nitrate (15%). The 43% of deposited nitrogen undergoing dry deposition in the UK is mostly (64%) NH$_3$. There are no network measurements of dry deposition, though dominance of NH$_3$ has also been inferred from derived dry deposition fluxes obtained using concentration and meteorology measurements and modelled dry deposition velocities at UK monitoring sites (Flechard et al., 2011; Tang et al., 2009).

3.2 Influence of Emission Controls on PM$_{2.5}$ and Public Health

Figure 4 includes the decrease in modelled PM$_{2.5}$ resulting from control measures to meet current legislation (4b) and from adopting maximum technically feasible measures (4c). Decline
in PM$_{2.5}$ in the CLE scenario is at most 2 $\mu$g m$^{-3}$ and typically 0.9-1 $\mu$g m$^{-3}$. MTF measures achieve up to 5 $\mu$g m$^{-3}$ decline in populated cities (London, Birmingham, Manchester, Leeds) and in locations with intensive industry (Welsh south coast) and large power plants (East Yorkshire). Greater decline in the MTF is due to combined decrease in point source emissions of SO$_2$, vehicular emissions of NO$_x$, and agricultural emissions of NH$_3$ (Figure 3). The largest decline is in April (3.7 $\mu$g m$^{-3}$ UK mean) and the smallest is in summer months (1.1-1.5 $\mu$g m$^{-3}$). The percent UK grids in Figure 4(a) that exceed the WHO guideline declines from 79% in the PD to 58% in the CLE and 36% in the MTF. Most of the decline is over Northern Ireland and Scotland north and south of the Central Belt for the CLE and for the MTF this spreads to the rest of Scotland, all of Cornwall and most of Wales.

**Figure 6.** Present-day and future UK adult premature mortality attributable to exposure to PM$_{2.5}$. Maps are administrative area early deaths for the PD (2019) (a) and future (2030) with CLE (b) and MTF (c) emission controls. Inset values are premature mortality estimated with the hybrid eSCHIF-Fusion model detailed in Section 2.3.

Figure 6 maps adult excess deaths attributable to exposure to PM$_{2.5}$ for all 3 scenarios in all UK administrative areas in the PD and by 2030 from adopting CLE or MTF measures. The eSCHIF portion of the hybrid curve (Eq. (1); Figure 1) is applied to 85% of GEOS-Chem grids for the PD and all grids for the CLE and MTF scenarios. PM$_{2.5}$ in all administrative areas exceeds the 2.5 $\mu$g m$^{-3}$ threshold for harm in the hybrid model (Figure 1). In the PD, UK annual premature mortality totals 48,625 (95% confidence interval (CI): 45,118-52,595) and on average 8% of premature adult deaths are attributable to exposure to PM$_{2.5}$. Greater London accounts for 10% of these (4,861; 95% CI: 4,549-5,247) and exceeds national totals for Scotland (3,673; 95% CI: 3,214-4,073), Wales (2,462; 95% CI: 2,270-2,660) and Northern Ireland (1,052; 95% CI: 934-1,156). Administrative areas other than Greater London that exceed a thousand excess deaths in the PD are Essex, Kent and Hampshire in southeast England and Lancashire in northwest England.
Lancashire and Hampshire fall below 1,000 with CLE measures and all except Greater London fall below 1,000 with MTF measures.

Annual adult excess deaths for the UK in the PD obtained using GEMM (Figure 1) are 4,608 more than the hybrid model at 53,233 (95% CI: 38,526-67,539), due to higher RRs in GEMM for PM$_{2.5} > 7$ μg m$^{-3}$ typical of populated cities in England (Figure 2(a)). The excess deaths we obtain for the UK in the PD with the hybrid model exceed previously published estimates of 28,969 for 2010 (Gowers et al., 2014) and 40,408 (95% CI: 30,867-45,050) for 2018 (Macintyre et al., 2023). These are both for adults ≥30 rather than ≥25 years old, but this difference has a small effect on burden of disease estimates, as premature mortality for the 25-30 age range is low (PHE, 2014). The curves used in past studies are compared to the hybrid model and GEMM in Figure 1. Incremental changes in risk used in those studies are on average 0.6% (Gowers et al., 2014) and 0.8% (Macintyre et al., 2023) per μg m$^{-3}$ PM$_{2.5}$ or RRs of 1.06 (Gowers et al., 2014) and 1.08 (Macintyre et al., 2023) at 10 μg m$^{-3}$. The hybrid model change in risk per μg m$^{-3}$ PM$_{2.5}$ ranges from almost 1% for PM$_{2.5} > 9.8$ μg m$^{-3}$ (the Fusion portion of the curve) to 0.5% at 5-9.8 μg m$^{-3}$ and 2.5% at 2.5-5 μg m$^{-3}$, due to variability in the eSCHIF curve gradient.

Decline in precursor emissions of PM$_{2.5}$ in the CLE results in a UK mean attributable fraction of 7% and total premature deaths of 41,874 (95% CI: 37,949-45,437) by 2030 or 6,751 avoided early deaths. In the MTF, premature deaths attributable to exposure to PM$_{2.5}$ is 6% of all nonaccidental premature deaths and totals 35,356 (95% CI: 29,882-40,015) by 2030. This is 13,269 avoided deaths, representing 27% of PD premature deaths attributable to PM$_{2.5}$ and twice that achieved with current legislation. The GEMM curve also yields a factor of 2 benefit to public health from adopting best available technologies over what is currently legislated.

The elderly (65+) account for most (86%) early nonaccidental deaths in the GBD data, so an aging UK population and recent epidemiological evidence for much greater health risk than the hybrid curve amongst the elderly exposed to PM$_{2.5}$ representative of concentrations in the UK would influence our estimates of avoided deaths. The UK Office of National Statistics projects there will likely be 2.5 million more elderly people in the UK in 2030 than in 2020 (https://www.ons.gov.uk/peoplepopulationandcommunity/populationandmigration/populationprojections/bulletins/nationalpopulationprojections/2020basedinterim; last accessed 2 June 2023), dampening the benefits of emission controls. The causal inference study by Wu et al. (2020) used 16 years of US Medicare data to estimate an RR of at least 1.23 at 10 μg m$^{-3}$ or on average a 2.3% decline in risk per μg m$^{-3}$ decrease in PM$_{2.5}$ amongst the elderly for PM$_{2.5} ≤ 12$ μg m$^{-3}$. This would substantially increase the number of premature elderly deaths attributable to PM$_{2.5}$ in the PD, but also increase the number of avoided early deaths due to emission controls.

### 3.3 Harm of Nitrogen Deposition and Ambient NH$_3$ to Sensitive Habitats

GEOS-Chem nitrogen deposited to all UK land totals 253 Gg N in the PD. This is lower than values from higher-resolution models and derived datasets. GEOS-Chem deposition is 25 Gg N or 9% less than is simulated for 2017 with a 5 km resolution CTM (Tomlinson et al., 2021) and 57 Gg N less than gridded mean nitrogen deposition from the CBED dataset (Section 2.4). According to GEOS-Chem, total deposited nitrogen is ~40% of the emitted terrestrial and aviation anthropogenic nitrogen (601 Gg N, Figure 3), suggesting that more than half (~60%) of the nitrogen emitted is exported offshore. As a result, decline in nitrogen deposition by 2030 is only
about a third of the decrease in terrestrial and aviation nitrogen emissions from adopting emission controls. For CLE measures, nitrogen deposited to UK land decreases by 27 Gg N or 31% of the decline in terrestrial and aviation emissions of 88 Gg N (Figure 3). NH₃ deposition increases in this scenario by 3 Gg N due to a 2% increase in NH₃ emissions. Decline in UK nitrogen deposition from MTF measures is 75 Gg N or 37% of the 205 Gg N decline in terrestrial and aviation emissions.

Figure 7. Impact of emission controls on excess nitrogen deposited to UK sensitive habitats. Maps are PD nitrogen deposition above sensitive habitat critical loads obtained with CBED (a) and the change in excess nitrogen deposition resulting from CLE (b) and MTF (c) control measures from GEOS-Chem. All units are kg N (ha sensitive habitat)⁻¹ a⁻¹. Grey shaded grids are below critical loads and red crosses identify those that fall below critical loads due to CLE (b) and MTF (c) controls. Inset numbers in (a) are percent UK land area, and total and average excess nitrogen, and in (b) and (c) the change in these relative to the PD. “pp” is percentage point.

Nitrogen deposited to sensitive habitats in excess of critical loads (Figure 2(a)) is shown in Figure 7(a) for the PD (2019). Excess nitrogen covers 95% of sensitive habitats, totals 106 Gg N and averages 14 kg N ha⁻¹. The largest exceedances of >35 kg N ha⁻¹ coincide with NH₃ emission hotspots associated with intensive livestock farming (Marais et al., 2021; Hellsten et al., 2008). By 2030, CLE controls decrease total nitrogen deposition to sensitive habitats by 6 Gg N and average exceedances by 1 kg N ha⁻¹ (Figure 7(b)) compared to decline of 18 Gg N total and 2 kg N ha⁻¹ average decline with MTF measures (Figure 7(c)). For both scenarios, decline in the extent of sensitive habitats exposed to excess nitrogen is modest at 4 percentage points for the CLE and 8 percentage points for the MTF. Almost all this decline is in northern Scotland. A similarly small decline (6 percentage points) is reported for a decade of emission controls from 2010 to 2019 (Rowe et al., 2022). Given that the decline in excess nitrogen deposition is <10% of the decline in emissions, an emissions reduction of at least 500 Gg N may be required to halve excess nitrogen.
deposition to 50 Gg N. This is ~80% of present-day emissions or more than twice that feasible with best available measures.

The extent of UK ambient air with NH$_3$ concentration > 1 $\mu$g m$^{-3}$, indicative of harm to bryophytes, is 73% in the PD. An increase in UK mean ambient NH$_3$ in the CLE of 8% increases UK area with NH$_3$ > 1 $\mu$g m$^{-3}$ to 75%. This is due to concurrent increase in NH$_3$ emissions (Figure 3) and decline in the efficacy of the NH$_3$ acidic aerosol sink (sulfate+nitrate decline by 24%). MTF controls on both NH$_3$ and acidic aerosol precursor emissions of SO$_2$ and NO$_x$ (Figure 3) cause decline in both NH$_3$ (by 13%) and sulfate+nitrate (by 46%), causing a modest decrease in the extent of NH$_3$ > 1 $\mu$g m$^{-3}$ to 69%. As NH$_3$ is semi-volatile, its emissions depend on multiple environmental factors. A warmer world may, for example, substantially increase NH$_3$ emissions. One estimate suggests a 5°C warmer world increases global NH$_3$ emissions by 30-70% (Sutton et al., 2013).

4 Conclusions

Particulate matter pollution even at the relatively low concentrations typical of the UK adversely affect human health and nitrogen pollution harms habitats sensitive to excess deposition and exposure to the phytotoxin ammonia (NH$_3$). We assess the potential health and ecosystem co-benefits that could be achieved in 2030 following legislative action or from adopting best available emission control measures using emissions projections, the GEOS-Chem model, high-spatial-resolution datasets, and up-to-date relationships between exposure and harm.

Legislative measures are most effective at targeting acidic aerosol (sulfate, nitrate) precursor emissions of sulfur dioxide (SO$_2$) and nitrogen oxides (NO$_x$), causing decline in fine particulate matter (PM$_{2.5}$) pollution and 6,751 avoided annual early deaths. The extent of the UK above the World Health Organization (WHO) 5 $\mu$g m$^{-3}$ guideline for long-term exposure to ambient PM$_{2.5}$ also decreases from 79% to 58%. If instead best available measures are adopted, the number of avoided annual early deaths doubles to 13,269 and less than half (36%) the UK exceeds the WHO guideline.

The benefits to habitats are near-negligible for current legislation and modest for adoption of best available measures. Both NH$_3$ abundance and the amount of nitrogen deposited as NH$_3$ increase with current legislation, as controls on agricultural sources are ineffective at decreasing NH$_3$ emissions and loss of NH$_3$ to acidic aerosols declines. Adoption of best available measures decreases NH$_3$ emissions, as these target major agricultural sources, but these are also insufficient for improving ecosystem health. A far greater (at least 80%) decline in UK nitrogen emissions may be needed to halve harmful nitrogen deposition than the 34% achieved with best available measures.

Author Contributions

EAM conducted the model simulations, analysed the output, calculated the ecosystem harm metrics and led manuscript preparation. JK processed the UKEAP rainwater concentration data and prepared 2050 emissions scalings files. KV calculated premature mortality. YL analysed the emissions data with supervisory support from GLu. GLu also aided in data visualization. NH and
ER provided critical load and CBED deposition data and guided EAM through its use. All co-authors provided editorial input.
