A Lyapunov-based Approach to Nonlinear Programming and Its Application to Nonlinear Model Predictive Torque Control

Kyung-hwan Choi and Christoph M. Hackl, Senior Member

Abstract—A tuning-parameter-free and matrix-inversion-free solution of nonlinear programming (NLP) problems is proposed. The key idea is to design an update law based on Lyapunov analysis to satisfy the first-order necessary conditions for optimality. To this aim, first, the Lyapunov function is defined as the summation of the norms of these conditions. Then, the desired optimization variables and Lagrange multipliers, which minimize the Lyapunov function, are found analytically, thereby rapidly approaching the necessary conditions. The proposed method neither requires tuning parameters nor matrix inversions; thus, it can be implemented easily with less iterations and computational load than conventional methods, such as sequential quadratic programming (SQP) and augmented Lagrangian method (ALM). The effectiveness of the proposed method is applied to and validated by using it to solve a nonlinear model predictive torque control (NMPTC) problem in electrical drives. The results are compared with those of SQP and ALM.

I. INTRODUCTION

Nonlinear programming (NLP) has been used in various applications as a powerful tool for optimizing the performance (of dynamical) systems [1]. However, solving NLP problems is still challenging because of the lack of a general analytical solution and the difficulty in designing effective numerical optimization processes [2].

Typical numerical approaches for NLP are sequential quadratic programming (SQP) and augmented Lagrangian method (ALM) [3]. SQP solves an NLP problem effectively when the NLP can be approximated as QPs and the iteration starts near the optimal solution. However, SQP is computationally expensive, especially for large-scale problems, because it involves the inversion of the Karush-Kuhn-Tucker (KKT) matrix [3]. In addition, two typical methods for SQP to handle inequality constraints, the interior point method and active-set method, may require a heavy computation at each iteration and numerous iterations, respectively, when the NLP includes many inequality constraints [3].

In contrast to SQP, ALM provides a simple but effective way to handle inequality constraints by adding penalty terms for the constraint violations to the objective function and by finding the penalty terms’ weights (i.e., Lagrange multipliers)

with a simple update law [3]. However, ALM uses multiple tuning parameters regarding handling the constraints, such as the barrier parameter and the constraint violation tolerance. Finding appropriate values for these parameters can be challenging and may require problem-specific tuning. In addition, ALM typically involves either the inversion of the Hessian or the approximation of the inverted Hessian, which is usually computationally demanding [4].

Besides SQP and ALM, most numerical approaches require (i) computationally demanding steps (such as the inversion of the KKT matrix or the Hessian or its approximation), (ii) tuning of multiple parameters (often problem-specific) and (iii) a large number of iterations until the optimization reaches a satisfactory solution. Therefore, this study presents a tuning-parameter-free and matrix-inversion-free numerical optimization method to solve NLPs. To this aim, a control perspective is adopted that interprets the numerical optimization process as a dynamical system such that typical control principles can be adopted to design an update law without introducing tuning parameters and utilizing matrix inversions. The key idea is to design an update law based on Lyapunov’s second method to meet the two first-order necessary conditions for optimality [3]. The Lyapunov function is defined as the summation of the norms of these two conditions. The desired optimization variables and Lagrange multipliers (which minimize the Lyapunov function) are analytically found which allows and guarantees the approach the necessary conditions rapidly.

The proposed method is called Lyapunov-based Nonlinear Programming (LBNLP). It can be implemented easily and with less iterations and computational load than conventional methods, such as SQP and ALM, due to its tuning-parameter-freeness and matrix-inversion-freeness; thus, it is particularly interesting and effective for nonlinear model predictive control (NMPC), which requires an NLP problem to be solved in real time within a short control period. The proposed method also allows the violation of constraints during the iteration process as ALM does, which is another desirable feature for NMPC with many inequality constraints. The update law of the proposed method can be directly used as the control law for NMPC because each iteration is at least suboptimal and converges towards the local solution rapidly.

Previous studies, including [5], have already explored control perspectives on numerical optimization, introducing various update laws. Nevertheless, the majority of these update laws were designed to address unconstrained optimization or relatively straightforward constrained optimization scenarios, such as convex problems. To the authors’ knowledge, using a
Lyapunov-based approach to solve an NLP and to implement NMPC has not been investigated yet.

II. PRELIMINARIES

This section provides preliminaries for this study: Section II-A defines a general formulation of NLPs, whereas Section II-B states the necessary conditions for optimality of NLPs. Section II-C describes SQP and ALM in more detail.

A. Nonlinear programming (NLP)

A general scalar formulation of NLP is given by

$$\min f(x)$$

subject to

$$c^e_j(x) = 0, \quad j \in E \subset \mathbb{N},$$

$$c^i_i(x) < 0, \quad i \in I \subset \mathbb{N},$$

where \( f: \mathbb{R}^n \to \mathbb{R}, c^e_j: \mathbb{R}^n \to \mathbb{R} \) and \( c^i_i: \mathbb{R}^n \to \mathbb{R} \)
are (at least) continuously differentiable and represent the objective function, the equality constraints for all \( j \in E \) (with dimension \( n_{eq} := |E| \)) and the inequality constraints for all \( i \in I \) (with dimension \( n_{in} := |I| \)), respectively. \( E \) and \( I \) are two finite sets of indices for the equality and inequality constraints, respectively. The vector \( x \in \mathbb{R}^n \) comprise the optimization variables. The goal is to find the optimal \( x^* := \arg\min_x f(x) \) subject to the constraints in (1). At least one of the functions in (1) must be nonlinear to obtain a nonlinear optimization problem.

B. Necessary Conditions for Optimality

The Lagrangian for the NLP in (1) is defined as

$$L(x, \lambda) := f(x) + \sum_{j \in E} \lambda^e_j c^e_j(x) + \sum_{i \in I} \lambda^i_i c^i_i(x)$$

$$= f(x) + \lambda^T c(x)$$

where \( \lambda^e_j \) and \( \lambda^i_i \) are the Lagrange multipliers for the equality and inequality constraints, respectively. For compactness all multipliers and constraints are collected in the Lagrangian multiplier vector \( \lambda := (\lambda^e_1, \ldots, \lambda^e_m, \lambda^i_1, \ldots, \lambda^i_m)^T \in \mathbb{R}^{n_{nc}} \) and the constraint vector \( c := (c^e_1, \ldots, c^e_m, c^i_1, \ldots, c^i_m)^T \in \mathbb{R}^{n_{nc}} \) where

$$n_c := n_{eq} + n_{in}$$

is the overall dimension of the constraints. For later, the active set \( \mathcal{A}(x) \) at any feasible \( x \) is introduced, which is the union of the set \( E \) and those indices of the active inequality constraints, i.e.,

$$\mathcal{A}(x) = E \cup \{ a \in I \mid c^i_a(x) = 0 \}.$$  

One constraint qualification for the necessary conditions is defined as follows:

**Definition 1** (Linear independence constraint qualification (LICQ) [3]). Given a feasible point \( x \) and the active set \( \mathcal{A}(x) \), the linear independence constraint qualification (LICQ) holds if the set of active constraint gradients \( \{ \nabla_x c_a(x) \mid a \in \mathcal{A}(x) \} \) is linearly independent.

The first-order necessary conditions for optimality, which provide the foundation for many numerical algorithms for NLP, are defined as follows.

**Theorem 1** (First-Order Necessary Conditions [3]). Suppose that \( x^* \) is a local solution of (1) and that the LICQ holds at \( x^* \). Then there is a Lagrange multiplier vector \( \lambda^* := (\lambda^e_1, \ldots, \lambda^e_m, \lambda^i_1, \ldots, \lambda^i_m)^T \in \mathbb{R}^{n_{nc}} \), such that the following conditions are satisfied at \( (x^*, \lambda^*) \):

$$\nabla_x L(x^*, \lambda^*) = 0,$$

(4a)

$$c^e_j(x^*) = 0, \quad \text{for all } j \in E,$$  

(4b)

$$c^i_i(x^*) \leq 0, \quad \text{for all } i \in I,$$  

(4c)

$$\lambda^i_i(x^*) = 0, \quad \text{for all } i \in I,$$  

(4d)

$$\lambda^e_j(x^*) = 0, \quad \text{for all } j \in E.$$

(4e)

The conditions (4) are known as the KKT conditions. Condition (4e) implies that the Lagrange multipliers corresponding to inactive inequality constraints are zero; thus, the first condition (4a) can be rewritten by omitting the terms for indices \( l \notin \mathcal{A}(x^*) \) as follows:

$$0 = \nabla_x L(x^*, \lambda^*) = \nabla_x f(x^*) + \sum_{a \in \mathcal{A}(x^*)} \lambda^e_a \nabla_x c_a(x^*).$$  

(5)

C. Typical Numerical Approaches to NLP

SQP and ALM are two typical numerical approaches which are described next to compare those to the proposed method.

1) SQP: SQP is an iterative method for NLP, solving a sequence of optimization subproblems, each of which is an approximation of the NLP as a quadratic programming (QP). Each subproblem is defined as follows [3]:

$$\min f(x[k]) + \nabla_x f(x[k])^T \Delta x[k]$$

$$+ \frac{1}{2} (\Delta x[k])^T H_L(x[k], \lambda[k]) \Delta x[k]$$

subject to

$$\nabla_x c_j(x[k])^T \Delta x[k] + c_j(x[k]) = 0, \quad j \in I,$$  

(6b)

$$\nabla_x c_i(x[k])^T \Delta x[k] + c_i(x[k]) \geq 0, \quad i \in I,$$  

(6c)

where \( \Delta x[k] := x[k+1] - x[k] \) (with actual iteration step \( k \in \mathbb{N} \)) and \( H_L(x, \lambda) := \nabla^2_x L(x, \lambda) \) denotes the Hessian of the Lagrangian with respect to \( x \). As the Hessian may neither be easy to compute nor is always positive definite within the admissible set, alternate choices for \( H_L \), such as full quasi-newton approximations and reduced-hessian approximations, can be used instead [3].

The solution of (6) can be obtained by solving

$$\begin{bmatrix}
H_L(x[k], \lambda[k]) & c_a(x[k]) \\
\nabla_x c_a(x[k]) & 0
\end{bmatrix} \begin{bmatrix}
\Delta x[k] \\
\Delta \lambda[k]
\end{bmatrix} = \begin{bmatrix}
-\nabla_x L(x[k], \lambda[k]) \\
-c_a(x[k])
\end{bmatrix} \quad (7)$$

for \( (\Delta x[k]^T, \Delta \lambda[k]^T)^T \) where \( \Delta \lambda[k] := \lambda[k+1] - \lambda[k], \ c_a^T(x) := (\nabla_x c_a(x))_a \in \mathbb{R}^{m \times n}, \ c_a(x) := [c_a(x)]_a \in \mathbb{R}^n \) and \( m \leq n_c \) is the number of active constraints. Each iteration \( k \) is well-defined when
the nonsingularity of the KKT matrix \( K(x[k], \lambda[k]) \) holds, which is a consequence of LICQ and the positive-definiteness of the Hessian.

SQP solves the NLP effectively when each subproblem approximates the NLP reasonably well. However, solving (7) involves the inversion of KKT matrix, which is computationally expensive. In addition, SQP does not allow for the violation of constraints and thus may struggle to find a feasible solution when the NLP includes many inequality constraints.

2) ALM: ALM is an iterative method for NLP, which combines aspects of both Lagrange multipliers and penalty methods to handle constraints by defining the augmented Lagrangian function as follows [3]:

\[
L_{\text{ALM}}(x, \lambda; \mu) := f(x) + \sum_{j \in E} \lambda_j c_j(x) + \frac{1}{2\mu} \sum_{j \in E} c_j^2(x)
+ \sum_{i \in I} \psi(c_i + \mu; \lambda_i; \mu),
\]

with barrier parameter \( \mu > 0 \) and function

\[
\psi(t, \sigma; \mu) := \begin{cases} \sigma t + t^2/(2\mu) & \text{if } t - \mu \sigma \leq 0, \\ -\mu t^2 / 2 & \text{otherwise}, \end{cases}
\]

weighting the inequality constraints \( c_i + \mu \) for all \( i \in \mathbb{I} \). Note that the augmented Lagrangian \( L_{\text{ALM}} \) differs from the standard Lagrangian (2) due to the squared terms of the equality constraints \( c_j(x) = c_j^0(x) \) for all \( j \in E \) and the sum of \( \psi(c_i + \mu; \lambda_i; \mu) \) for all \( i \in \mathbb{I} \).

The vector \( x[k] \) is updated to minimize the augmented Lagrangian function \( L_{\text{ALM}} \) for given \( \lambda[k] \) and \( \mu[k] > 0 \) as follows

\[
\min_{x[k]} L_{\text{ALM}}(x[k], \lambda[k]; \mu[k]).
\]

Methods of unconstrained optimization, such as Newton and quasi-Newton methods, are usually employed to solve this problem [4]. The estimated Lagrange multipliers \( \lambda[k] \) are updated based on the extent of constraint violation, i.e.

\[
\begin{align*}
\lambda_j[k + 1] & := \lambda_j[k] + \frac{c_j(x[k])}{\mu[k]}, & \forall j \in E, \\
\lambda_i[k + 1] & := \max \left( \lambda_i[k] + \frac{c_i + \mu}{\mu[k]}, 0 \right), & \forall i \in I.
\end{align*}
\]

The barrier parameter \( \mu[k] \) is adjusted during the iterations to balance convergence and numerical stability.

This separate update of optimization variables and Lagrange multipliers can lead to more efficient and scalable solutions. Particularly, this approach allows for the violation of constraints during the iteration process and thus can handle infeasible starting points and inequality constraints. However, ALM uses multiple tuning parameters to handle the constraints, such as the barrier parameter and others used for practical implementation [3]. Finding appropriate values for these parameters can be challenging and may require problem-specific tuning. In addition, ALM typically involves either the inversion of the Hessian or the approximation of the inverted Hessian; which is computationally demanding.

III. LYAPUNOV-BASED NONLINEAR PROGRAMMING (LBNLP)

This section presents the novel Lyapunov-based approach for solving NLP. Section III-B presents an update law derived from Lyapunov analysis including a proof of convergence. Section III-C proposes an implementation algorithm for the proposed method and Section III-D describes beneficial properties of the proposed method in comparison to SQP and ALM.

A. (Re-)Introduction of crucial definitions and facts

For later, gradient

\[
g_L(x, \lambda) := \nabla_x \lambda L(x, \lambda) \quad \text{and Hessian}
\]

\[
H_L(x, \lambda) := \nabla_x g_L(x, \lambda) := \nabla_x^2 \lambda L(x, \lambda)
\]

of the Lagrangian \( L \) as in (2) with respect to \( x \) are required. Moreover, note that the following hold

\[
\begin{align*}
\nabla_x \lambda g_L(x, \lambda) & \equiv C(x) \in \mathbb{R}^{n \times n}, \\
\nabla^2 \lambda L(x, \lambda) & \equiv \sigma(x) \in \mathbb{R}^{n \times n}, \quad \sigma(x) := \begin{cases} 2 & \text{if } c(x) > 0, \\ 0 & \text{otherwise.} \end{cases}
\end{align*}
\]

Furthermore, for \( C \in \mathbb{R}^{n \times n} \),

\[
|| C - I_n || = \max | \sigma_i(C) - 1 |
\]

where \( \sigma_i(\cdot) \) denotes the \( i \)th eigenvalue of its input matrix and \( \sigma_1(\cdot) > \cdots > \sigma_n(\cdot) \). For \( x \in \mathbb{R} \) and \( y \in \mathbb{R} \), the following holds \( (x - y)^2 = x^2 - 2xy + y^2 \geq 0 \), which gives

\[
x y \leq \frac{1}{2} (x^2 + y^2).
\]

Finally, the following Lyapunov function candidate

\[
V := \frac{1}{2} g_L(x, \lambda)^\top C(x) g_L(x, \lambda) + \frac{1}{2} c(x)^\top c(x)
\]

will play a crucial role with its time derivative

\[
\begin{align*}
\frac{d}{dt} V & \equiv \frac{d}{dt} \left( g_L(x, \lambda)^\top H_L(x, \lambda) + C(x) \Delta x \right) \\
& \approx \frac{d}{dt} \left( g_L(x, \lambda)^\top H_L(x, \lambda) \right) + C(x) \frac{\Delta x}{\Delta t} \\
& \approx \frac{d}{dt} \left( g_L(x, \lambda)^\top C(x) \right) + C(x) \frac{\Delta x}{\Delta t} \\
& = \frac{1}{\Delta t} \left( g_L(x, \lambda)^\top K(x, \lambda) \right) \Delta x,
\end{align*}
\]

where, in the second step, the approximations \( \frac{d}{dt} x \approx \frac{\Delta x}{\Delta t} \) and \( \frac{d}{dt} \lambda \approx \frac{\Delta x}{\Delta t} \) were used with \( \Delta t > 0 \) and \( K(x, \lambda) \) is as in (7). Clearly, it is well known from Lyapunov’s second method [6], that if \( \frac{d}{dt} V < 0 \) for all non-zero \( (x, \lambda) \), the system is stable; which implies for this approach here that the iteration algorithm is not diverging.
B. Update law

Two update laws will be presented: one existing and one proposed. To do so, define (i) the vector of Lagrange multipliers of active constraints as \( \lambda_A := [\lambda_{a}]_{a \in A} \in \mathbb{R}^m \) (with \( m \leq n_c \)), (ii) the active constraint vector as \( c_A(x) := [c_a(x)]_{a \in A} \in \mathbb{R}^m \) and (iii) its derivative with respect to \( x \) as \( C_A(x) \in \mathbb{R}^{n \times m} \). Hence, only active constraints are considered in the following which will allow to invoke the LICQ (see Definition 1).

1) Update law 1 (Existing): The first update law is given by
\[
(\Delta x) \frac{\Delta \lambda_A}{\Delta t} := -\alpha K^\top (x, \lambda_A) \left( g_L(x, \lambda_A) + c_A(x, \lambda_A) \right) =: -\alpha \left( p_x, p_\lambda \right),
\]
with step length \( \alpha > 0 \) and search directions \( p_x \) and \( p_\lambda \) along \( x \) and \( \lambda \), respectively. Inserting (20) into the time derivative (20) of the Lyapunov function (17) yields
\[
\frac{d}{dt} V(20) \geq \frac{1}{\alpha} \sum_{a \in A} g_a \left( g_L + \frac{\Delta \lambda_A}{\Delta t} \right) \left( g_L + C_A \frac{\Delta \lambda_A}{\Delta t} \right) - \frac{1}{\alpha} \sum_{a \in A} g_a^\top g_a.
\]
This update law was introduced in [5] as the discrete-time Jacobian matrix transpose method (DJT).

2) Update law 2 (Proposed): Assume the inverse of \( H_L(x, \lambda) \) exists but does not need to be known. Define
\[
B = \{ \beta \in \mathbb{R} \mid \| \beta H_L^{-1} - I_n \| \leq 1, \beta \geq 0 \}. \tag{23}
\]
For \( \alpha > 0 \) and \( \beta \in B \), the second update law is given by
\[
\left( \Delta x \right) \Delta \lambda_A := -\alpha \left[ K^\top + \left( \begin{array}{cc} 0_{n \times n} & 0_{n \times n} \\ \lambda \lambda & -2 \beta \lambda \end{array} \right) \right] \left( g_L + c_A \right) \tag{24}
\]
Evaluating the time derivative (20) of the Lyapunov function (17) for (24) yields
\[
\frac{d}{dt} V(20) \geq \frac{1}{\alpha} \sum_{a \in A} g_a^\top g_a \left( \frac{\Delta \lambda_A}{\Delta t} + C_A \frac{\Delta \lambda_A}{\Delta t} \right) - \frac{1}{\alpha} \sum_{a \in A} g_a^\top g_a
\]
and
\[
\leq \frac{1}{\alpha} \sum_{a \in A} g_a^\top g_a \left( \frac{\Delta \lambda_A}{\Delta t} + C_A \frac{\Delta \lambda_A}{\Delta t} \right) - \frac{1}{\alpha} \sum_{a \in A} g_a^\top g_a
\]
where (26) is derived invoking the following argument
\[
g_a^\top H_L (\beta H_L^{-1} - I_n) c_A \leq \left\| g_a^\top H_L \right\| \left\| \beta H_L^{-1} - I_n \right\| \left\| C_A c_A \right\|
\]
and (23) follows. A possible selection of \( \beta \) depends on the eigenvalues of \( H_L \) according to (15). A suggestion is given as follows
\[
\beta := \begin{cases} \sigma_1 (H_L) & \text{if } \sigma_1 (H_L) \geq 0 \\ \sigma_n (H_L) & \text{if } \sigma_n (H_L) \leq 0 \\ 0 & \text{else.} \end{cases}
\]
Please note that, for a proper choice of \( \beta \), rough knowledge of \( H_L \) is required.

3) Comparison of Update laws 1 and 2: \( \Delta \lambda_A \) of update law 1 depends only on \( g_L \) not on \( c_A \) (see the elements of matrix \( K \) as defined in (7)). Thus, update law 1 may not effectively handle the constraints even though the Lyapunov analysis proved the convergence. Referring to ALM, where the update of \( \lambda_A \) solely depends on \( c_A \) (see (11)), update law 2 was derived to include an additional term of \( 2 \alpha \beta c_A \) to allow for updating \( \lambda_A \). Update law 1 is considered a special case of update law 2 with \( \beta = 0 \).

The effectiveness of including the additional term can be shown by analyzing the time derivative (25) of the Lyapunov function for two extreme cases. When \( \beta = 0 \) (i.e., update law 1), the upper bound of inequality (25) is derived as (26). When \( \beta \) is designed to make the last term in (25) negligibly small (i.e., ideal case of update law 2), the upper bound of inequality (25) approximately becomes
\[
\frac{d}{dt} V(25) \leq -\frac{1}{\alpha} \left( g_L \right)^\top \left( H_L \left( \beta H_L^{-1} - I_n \right) C_A \right) g_L - \frac{1}{\alpha} \left( g_L \right)^\top C_A C_A c_A
\]
which shows a stronger convergence than update law 1 for both \( g_L \) and \( c_A \). Furthermore, if \( H_L \) has full rank and the active set \( A(x) \) satisfies the LICQ (i.e., \( H_L \) and \( C_A \) are positive definite), then exponential decay is shown by
\[
\frac{d}{dt} V \leq -\frac{1}{\alpha} \left( g_L \right)^\top \left( H_L \left( \beta H_L^{-1} - I_n \right) C_A \right) g_L - \frac{1}{\alpha} \left( g_L \right)^\top C_A C_A c_A
\]
where \( P \) is positive definite. The exponential decay rate is \( \frac{2}{\alpha} \lambda_{\min} (P) \). The optimization variables and Lagrange multipliers are updated as follows:
\[
x[k + 1] \leftarrow x[k] + \Delta x[k], \tag{28a}
\]
\[
\lambda_A[k + 1] \leftarrow \lambda_A[k] + \Delta \lambda_A[k]. \tag{28b}
\]
Because the update laws are implemented in discrete time, the step length \( \alpha \) should be chosen to ensure their stability. The step length, proposed in Lemma 2.4 in [5], is adopted in this study as follows
\[
\alpha[k] := \left. \frac{x[k]^\top p_x[k] + \lambda_A[k]^\top p_\lambda[k]}{\| p_x[k] \|^2 + \| p_\lambda[k] \|^2} \right|_{\| p_x[k] \|^2 + \| p_\lambda[k] \|^2
\]
where \( p_x \) and \( p_\lambda \) denote the search directions of the respective update law (see (21) and (24)).

C. Algorithm

The proposed method (update law 2), termed LBNLP, is implemented by Algorithm 1. This algorithm consists of the update law and the more actions as follows:

- Restrain the Lagrange multipliers for the inequality constraints greater than or equal to 0;
- Remove the inequality constraints with \( \lambda_i = 0 \) from the active set \( A(x) \); and
- Add the inequality constraints with \( c_i(x) < 0 \) to the active set \( A(x) \).
Algorithm 1: LBNLP (Update law 2)

1. Compute a feasible starting point \((x[0], \lambda[0])\);
2. Set the initial active set \(\mathcal{A}(x[0])\);
3. for \(k = 0, 1, 2, \ldots\) do
   4. Compute \(\Delta x[k]\) and \(\Delta \lambda_k[k]\) using (24) and (29);
   5. \(x[k+1] \leftarrow x[k] + \Delta x[k]\);
   6. \(\lambda_k[k+1] \leftarrow \lambda_k[k] + \Delta \lambda_k[k];\)
   7. \(\lambda_{i}[k+1] \leftarrow \max(\lambda_i[k]+1, 0), i \in \mathcal{A}(x[k]) \cap \mathbb{E};\)
   8. \(\lambda_{i}[k+1] \leftarrow \lambda_{i}[k], i \notin \mathcal{A}(x[k]);\)
   9. \(\mathcal{A}(x[k+1]) \leftarrow \mathcal{A}(x[k]) \setminus \{j\},\) for all \(j \in \mathcal{A}(x[k])\)
      with \(\lambda_{j}[k+1] = 0;\)
   10. \(\mathcal{A}(x[k+1]) \leftarrow \mathcal{A}(x[k]) \cup \{j\},\) for all \(j \notin \mathcal{A}(x[k])\)
        with \(\lambda_{j}[k+1] < 0;\)

These actions ensure that the three necessary KKT conditions for the inequality constraints, as specified in (4c), (4d), and (4e), are easily satisfied, despite not being explicitly incorporated into the Lyapunov function (17).

D. Comparison of Properties of LBNLP, SQP, and ALM

Equations (24), (27), and (29) show that the proposed method is matrix-inversion-free and tuning-parameter-free. There is one more to note. The update law for \(\lambda_k\), (24), is similar to that of ALM, (11), in that both include information on constraint violations (i.e., \(c_k\)) but differs in that (24) also includes information on \(g_L(= \nabla_x L(x, \lambda))\). The inclusion of \(g_L\) allows the appropriate update of \(\lambda_k\) without using tuning parameters as in ALM.

The properties of the proposed method are summarized in Table I as compared with SQP and ALM. Note that this comparison only considers the case for local convergence.

IV. APPLICATION OF LBNLP TO NMPTC

This section discusses the possible application of the proposed LBNLP to NMPC in general and NMPTC specifically: Section IV-A explains two different formulations of a general NMPC problem, whereas Section IV-B introduces NMPTC of electrical drives. Section IV-C provides validation results of the proposed method for the NMPTC problem and compares those to the results obtained by SQP and ALM.

A. Nonlinear model predictive control (NMPC)

1) Problem statement: The NMPC formulation [7] is

\[
\begin{align*}
\mathbf{u}^* &= \arg \min_{\mathbf{u}[k+1], \ldots, \mathbf{u}[k+N]} \sum_{n=1}^{N-1} \left[ q(\mathbf{x}[k+n], \mathbf{u}[k+n]) \right] \\
& \quad + w q(\mathbf{x}[k+n], \mathbf{u}[k+n]) \\
\text{subject to} & \quad \mathbf{x}[k+n+1] = \mathbf{f}(\mathbf{x}[k+n], \mathbf{u}[k+n]), \\
& \quad \mathbf{y}[k+n] = \mathbf{g}(\mathbf{x}[k+n], \mathbf{u}[k+n]), \\
& \quad \mathbf{h}(\mathbf{x}[k+n], \mathbf{u}[k+n]) \geq 0, \ n = 1, \ldots, N
\end{align*}
\]

where arguments \(k, k+1, \ldots, k+N\) denote (succeeding) sampling instants until the prediction horizon \(1 \leq n \leq N\); \(x, u, y\) denote system state, control input, and output vector, respectively; \(e := y_{\text{ref}} - y\) represents the tracking error (difference between output \(y\) and reference signal \(y_{\text{ref}}\); \(F\) and \(Q\) are symmetric positive definite matrices (of appropriate size) weighting final and preceding tracking errors; \(q(\cdot, \cdot)\) represents the control effort function; the weighting factor \(w\) quantifies the relative importance of the control effort function in comparison to the tracking error terms; and \(f(\cdot, \cdot), g(\cdot, \cdot), \) and \(h(\cdot, \cdot)\) denote functions of the state, output, and (in)equality constraints, respectively.

This NMPC formulation can describe several optimal tracking control problems of various applications [7]. However, it requires an appropriate tuning of the matrices \(F\) and \(Q\), and function \(q\) to guarantee stability and convergence of the tracking error to zero due to the trade-off between the tracking error and control effort terms in the objective function [7]. To avoid this tuning a reformulation of the problem statement is beneficial which is introduced next.

2) NMPC reformulation: The NMPC problem (30) can be reformulated by considering the (final) tracking error as equality constraint in contrast to considering it in the objective function (30a) which resolves the inevitable weighting trade-off between tracking error and control effort terms in (30a) [8]. The NMPC reformulation is given by

\[
\begin{align*}
\mathbf{u}^* &= \arg \min_{\mathbf{u}[k+1], \ldots, \mathbf{u}[k+N]} \sum_{n=1}^{N-1} q(\mathbf{x}[k+n], \mathbf{u}[k+n]) \\
\text{subject to} & \quad \mathbf{x}[k+n+1] = \mathbf{f}(\mathbf{x}[k+n], \mathbf{u}[k+n]), \\
& \quad \mathbf{y}[k+n] = \mathbf{g}(\mathbf{x}[k+n], \mathbf{u}[k+n]), \\
& \quad \mathbf{h}(\mathbf{x}[k+n], \mathbf{u}[k+n]) \geq 0, \ n = 1, \ldots, N \\
& \quad e[k+N] = 0
\end{align*}
\]

There is no guarantee to satisfy the equality constraint in (31e) (i) if the reference signal \(y_{\text{ref}}\) cannot be attained within the prediction horizon no matter what control effort is admissible, or (ii) if a numerical optimization method for this problem does not allow violation of the equality constraint. However, if a numerical optimization method allows for the violation of constraints like the proposed LBNLP method, this NMPC problem can (approximately) be solved even if the reference signal cannot be attained within the prediction horizon.
horizon. Note that SQP does not allow for the violation of constraints whereas ALM does. However, using the proposed LBNLP is even more advantageous than using ALM (recall Table I and see validation in the next Subsection IV-B).

**Remark 1.** For NMPC convergence, it is beneficial if the reference signal is a smooth function as this helps to satisfy the (in)equality constraints at all sampling instants [9].

### B. Nonlinear model predictive torque control (NMPTC)

The NMPTC problem presented in [10] is re-discussed to apply and validate the proposed LBNLP method. The NMPTC here is used to solve the Maximum-Torque per Current (MTPC) and Field Weakening (FW) problems – subproblems of optimal feedforward torque control (OFTC) [11] of permanent magnet synchronous machines (PMSMs) modelled by the nonlinear dynamics

$$\begin{align*}
\frac{d}{dt} \omega_m &= \frac{2}{3\pi\tau_p} (i_s^d \phi_m + \frac{d}{dt} \psi_s^d - m_i), \\
\frac{d}{dt} \phi_m &= \omega_m
\end{align*}$$

with $J := \begin{bmatrix} 0 & -1 \end{bmatrix}$, stator voltages $u_s^d := (u_s^d, u_s^q)^T$, stator currents $i_s^d := (i_s^d, i_s^q)^T$, stator resistance matrix $R_s^d := R_s^d(i_s^d, \omega_p, \phi_p, \phi) = (R_s^d)^T > 0$, stator flux linkages $\psi_s^d := (\psi_s^d, \psi_s^q)^T := \psi_s^d(i_s^d, \omega_p, \phi_p, \phi)$, load torque $m_i$, Clarke transformation factor $\kappa \in \{2/3, \sqrt{3}/3\}$ [12, Ch. 14], electrical angular velocity $\omega_p = n_p\omega_m$ (i.e., the product of pole pair number $n_p$ and mechanical angular velocity $\omega_m$) and machine torque $m_m := \frac{2}{3\pi\tau_p} n_p (i_s^d)^2 \omega_m$. Note that stator resistance matrix $R_s^d(i_s^d, \omega_p, \phi_p)$ and stator flux linkages $\psi_s^d(i_s^d, \omega_p, \phi_p, \phi)$ may vary with current, frequency and angle, respectively [13].

For this paper, only the dependency on the currents $i_s^d$ is considered. Moreover, the machine torque $m_m$ represents the average torque neglecting the dependencies on rotor position or iron losses [14]. Stator voltages and currents are limited to [13]

$$\|u_s^d\| \leq \overline{u}_m \text{ and } \|i_s^d\| \leq \overline{i}_m$$

(33)

To protect the machine (isolation and thermal capacity). Rewriting (32) as current dynamics and discretizing² yields

$$\begin{align*}
\dot{i}_s^d[k+1] &= T_s L_s^d i_s^d[k] - R_s^d i_s^d[k] + \frac{d}{dt}\psi_s^d[k], \\
-\omega_m[k] J \psi_s^d[k] + \dot{\psi}_s^d[k] &= f(i_s^d[k], u_s^d[k]), \\
\omega_m[k+1] &:= \frac{T_s}{\tau_m} (m_m[k] - m_i[k]) + \omega_m[k], \\
\phi_m[k+1] &:= T_s \omega_m[k] + \phi_m[k],
\end{align*}$$

(34)

where, to simplify notation, the following conventions were and will be applied for differential indutance matrix

$$L_s^d[k] := L_s^d(i_s^d[k]) = L_s^d(i_s^d[k])^T > 0,$$

flux linkages $\psi_s^d[k] := \psi_s^d(i_s^d[k])$ and machine torque $m_m[k] := \frac{2}{3\pi\tau_p} n_p (i_s^d[k])^2 \omega_m[k]$.

²Invoking the Euler forward method leads to $\frac{d}{dt} x(t) \approx (x[k+1] - x[k]) / T_s$ with sampled quantity $x[k] \approx x(kT_s)$ at sampling instant $k \in \mathbb{N}$ and sampling frequency $T_s > 0$.

For MTPC (or MTPA³) operation, the minimization of Joule losses $(i_s^q[k])^T R_s^q i_s^q[k]$ is crucial and usual a prediction horizon of $N = 1$ is sufficient [10], [11]. With these losses, the right-hand side $f(i_s^d[k], u_s^d[k])$ of the current dynamics in (34) and the physical machine constraints in (33), the NMPTC problem can directly be formulated:

$$\begin{align*}
u^* := \arg \min_{u_s^d[k+1]} \frac{d}{dt} i_s^d[k+1] + R_s^d i_s^d[k+1] \quad (35a)
subject to \quad
x[k+1] := i_s^d[k+1] = f(i_s^d[k], u_s^d[k]),
\end{align*}$$

(35b)

$$y[k+1] := m_m[k+1] = \frac{2}{3\pi n_p \tau_p} (i_s^d[k+1]^T J \psi_s^d[k+1]),$$

(35c)

$$h(x[k+1], u[k+1]) := \left( \frac{\hat{u}_\text{max}^2}{i^2} - \|u_s^d[k+1]\|^2 \right) \geq 0_2,$$

(35d)

$$e[k+1] := m_{\text{m,ref}}[k+1] - m_m[k+1] = 0$$

(35e)

where $x[k+1] := i_s^d[k+1]$ and $u[k+1] := u_s^d[k+1]$ denote the stator current and voltage vectors at the next sampling instant, respectively. Clearly, NMPTC in (35) is a subproblem of the reformulated NMPC in (31).

### C. Validation

For the validation of the proposed LBNLP, the NMPTC problem is implemented for an anisotropic PMSM with affine stator flux linkage

$$\psi_s^d := \begin{bmatrix} L_s^d & 0 \\ 0 & L_s^q \end{bmatrix} i_s^d + \begin{bmatrix} \psi_{s^d}^q \\ 0 \end{bmatrix},$$

where $L_s^d$ and $L_s^q$ denote the $d$- and $q$-axis inductions, respectively. $\psi_{s^d}^q$ denotes the flux linkage of the permanent magnets. The machine parameters are $R_s = 25\Omega$, $L_s^d = 0.45mH$, $L_s^q = 0.66mH$, $\psi_{s^d}^q = 0.0563Wb$, $n_p = 8$, $\hat{u}_\text{max} = 56.5V$, $\hat{i}_\text{max} = 70A$.

The NMPTC problem as stated in (35) was implemented and numerically solved in MATLAB 2023a by SQP, ALM, and the proposed LBNLP, respectively. The reference torque $m_{\text{m,ref}}$ was given with 30 Nm. Two different electrical angular velocities $\omega_p$, at 840 rad/s and 1090 rad/s, were simulated to examine the cases when the inequality (voltage) constraint is inactive and active, respectively.

ALM and the proposed method solved the problem in the formulation of (31), while SQP solved the problem in the formulation of (30) because SQP did not guarantee to handle the equality constraint (31e). SQP was implemented by the ‘fmincon’ function available in MATLAB, which is a well-known NLP solver, with the option of ‘sqp’. Three different values were used for the weighting factor $w \in \{10^{-4}, 10^{-2}, 10^0\}$, to examine the trade-off between the tracking error terms and control effort term in the objective function. ALM was implemented by solving (10) using Newton’s method with an iteration termination condition of $\|\nabla_\lambda L_{\text{ALM}}\| \leq 10^{-4}$. Three different values were used for

³Maximum Torque per Ampere.
Fig. 1. NMPC results obtained using SQP with $w = 10^{-4}, 10^{-2}, \text{ and } 10^{0}$ for the conditions of (a) $w_p = 840 \text{ rad/s}$ and (b) $w_p = 1090 \text{ rad/s}$.

The NMPC results obtained using ALM are presented in Fig. 2. Similar to the SQP method, ALM achieves a desirable state trajectory exclusively with $\mu = 10^{-2}$. Smaller and larger values of $\mu$ lead to unstable trajectories and failure to meet the tracking condition; however, it exhibits unacceptable transient behavior due to the violation of the inequality constraint. This result demonstrates the superiority of LBNLP over the existing update law 1 in terms of constraint handling.

For the condition of $\omega_p = 1090 \text{ rad/s}$, the computation times were $1.76 \pm 0.20 \text{ ms}$ for SQP with $w = 10^{-2}$, $25.8 \pm 9.2 \mu s$ for ALM with $\mu = 10^0$, and $12.8 \pm 2.1 \mu s$ for LBNLP, respectively. These results were obtained from one hundred simulation runs, where the computation time was measured using MATLAB’s ‘tic-toc’ function. The computation times of SQP were approximately one hundred times greater than those of ALM and the proposed method, which is probably due to the inversion of the KKT matrix for SQP and multiple iterations to obtain reasonable solutions. The average computation time of ALM was approximately twice greater than that of the proposed method. This is because
ALM uses multiple iterations to guarantee the convergence of Newton’s method. This result verifies that the proposed method, which is matrix-inversion-free and does not require large numbers of iterations, is computationally efficient.

V. CONCLUSION

This study presented a novel numerical optimization method to solve NLP. The method is based on a Lyapunov approach to reach the necessary conditions for optimality. The advantage of using the Lyapunov approach is that the update law can be derived in a tuning-parameter-free and matrix-inversion-free manner; thus, the proposed method can be implemented easily and with less iteration and computation time than conventional methods, such as SQP and ALM. The effectiveness of the proposed method was validated by using it to solve an NLP problem, which was an NMPC problem for optimal torque control of PMSMs, and comparing it with SQP and ALM. Future studies will include measurement results to also validate the proposed method experimentally.
